

Dear Author,

Here are the proofs of your article.

- You can submit your corrections **online**, via **e-mail** or by **fax**.
- For **online** submission please insert your corrections in the online correction form. Always indicate the line number to which the correction refers.
- You can also insert your corrections in the proof PDF and **email** the annotated PDF.
- For fax submission, please ensure that your corrections are clearly legible. Use a fine black pen and write the correction in the margin, not too close to the edge of the page.
- Remember to note the **journal title**, **article number**, and **your name** when sending your response via e-mail or fax.
- **Check** the metadata sheet to make sure that the header information, especially author names and the corresponding affiliations are correctly shown.
- **Check** the questions that may have arisen during copy editing and insert your answers/ corrections.
- **Check** that the text is complete and that all figures, tables and their legends are included. Also check the accuracy of special characters, equations, and electronic supplementary material if applicable. If necessary refer to the *Edited manuscript*.
- The publication of inaccurate data such as dosages and units can have serious consequences. Please take particular care that all such details are correct.
- Please **do not** make changes that involve only matters of style. We have generally introduced forms that follow the journal's style. Substantial changes in content, e.g., new results, corrected values, title and authorship are not allowed without the approval of the responsible editor. In such a case, please contact the Editorial Office and return his/her consent together with the proof.
- If we do not receive your corrections **within 48 hours**, we will send you a reminder.
- Your article will be published **Online First** approximately one week after receipt of your corrected proofs. This is the **official first publication** citable with the DOI. **Further changes are, therefore, not possible.**
- The **printed version** will follow in a forthcoming issue.

Please note

After online publication, subscribers (personal/institutional) to this journal will have access to the complete article via the DOI using the URL: [http://dx.doi.org/\[DOI\]](http://dx.doi.org/[DOI]).

If you would like to know when your article has been published online, take advantage of our free alert service. For registration and further information go to: <http://www.link.springer.com>.

Due to the electronic nature of the procedure, the manuscript and the original figures will only be returned to you on special request. When you return your corrections, please inform us if you would like to have these documents returned.

ABSTRACT

Soil respiration is the largest single efflux in the global carbon cycle and varies in complex ways with climate, vegetation, and soils. The suppressive effect of nitrogen (N) addition on soil respiration is well documented, but the extent to which it may be moderated by stand age or the availability of soil phosphorus (P) is not well understood. We quantified the response of soil respiration to manipulation of soil N and P availability in a full-factorial N x P fertilization experiment spanning 10 years in 13 northern hardwood forests in the White Mountains of New Hampshire, USA. We analyzed data for 2011 alone, to account for potential treatment effects unique to the first year of fertilization, and for three 3-year periods; data from each 3-year period was divided into spring, summer, and fall. Nitrogen addition consistently suppressed soil respiration by up to 14% relative to controls ($p \leq 0.01$ for the main effect of N in 5 of 10 analysis periods). This

response was tempered when P was also added, reducing the suppressive effect of N addition from 24 to 1% in one of the ten analysis periods (summer 2012–2014, $p = 0.01$ for the interaction of N and P). This interaction effect is consistent with observations of reduced foliar N and available soil N following P addition. Mid-successional stands (26–41 years old at the time of the first nutrient addition) consistently had the lowest rates of soil respiration across stand age classes ($1.4\text{--}6.6 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$), and young stands had the highest ($2.5\text{--}8.5 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$). In addition to these important effects of treatment and stand age, we observed an unexpected increase in soil respiration, which doubled in 10 years and was not explained by soil temperature patterns, nutrient additions, or increased in fine-root biomass.

Key words: MELNHE; multiple element limitation; fine-root biomass; Hubbard Brook; Bartlett; Jeffers Brook.

55 **HIGHLIGHTS**

56

- 57 • Nitrogen addition reduced soil respiration by up to 14% in northern hardwood forests.
- 58
- 59 • Soil respiration was lowest in mid-successional stands (26-41 years since harvest).
- 60
- 61 • Soil respiration doubled in 10 years and was not explained by increasing temperature.
- 62

63 **INTRODUCTION**

64 The largest fluxes in the global carbon cycle are the
 65 movements of carbon into and out of terrestrial
 66 ecosystems by photosynthesis and respiration,
 67 respectively (Le Quéré and others 2018). In tem-
 68 perate broadleaf forests, about 70% of ecosystem
 69 respiration comes from soils (Goulden and others
 70 1996; Janssens and others 2001; Law and others
 71 1999; Ryan and Law 2005), and rates of soil res-
 72 piration change as forests progress through suc-
 73 cessional development. Because soil temperature is
 74 one of the primary drivers of soil respiration (Luo
 75 and others 2001; Bronson and others 2008; Bond-
 76 Lamberty and Thomson 2010), young stands ex-
 77 hibit high rates of soil respiration prior to canopy
 78 closure (Ewel and others 1987; Xiao and others
 79 2014). Fine-root biomass, which reaches a maxi-
 80 mum at canopy closure (Peichl and Arain 2006;
 81 Helmisaari and others 2002), likely contributes to
 82 the high soil respiration associated with young
 83 stands as well. Available nitrogen (N) decreased for
 84 the first 20 years following clearcutting and
 85 reached a maximum roughly 50 years later in as-
 86 pen stands in Michigan (White and others 2004).
 87 Perhaps as a result of these multiple factors, studies
 88 of soil respiration across stand age have come to
 89 inconsistent conclusions: Some studies report in-
 90 creases in soil respiration with age (Gough and
 91 others 2005), some report a decrease (Ewel and
 92 others 2011; Tedeschi and others 2006), and an-
 93 other reports interannual variation in the effect of
 94 stand age on soil respiration (Irvine and Law 2002).
 95 On top of these developmental factors, seasonal
 96 changes in microbial communities (Sorensen and
 97 others 2018) and rates of root growth (Abramoff
 98 and Finzi 2016) could also be expected to affect soil
 99 respiration.

100 Generally, rates of carbon partitioning below-
 101 ground—and therefore soil respiration—are higher
 102 in low-fertility forests because greater effort is re-
 103 quired for soil resource acquisition (Bae and others
 104 2015; Bloom and others 1985; Gower and others
 105 1994; Litton and others 2007). Relationships be-

tween N availability and forest carbon cycling are 106
 particularly well studied, and much of that research 107
 has demonstrated reduced soil respiration with in- 108
 creased N availability (Bowden and others 2004; 109
 Burton and others 2004; Bae and others 2015; 110
 Kang and others 2016). Mechanistically, responses 111
 of the soil priming effect to N addition can explain 112
 the suppression of soil respiration: when soil 113
 nutrients are scarce, autotrophic inputs of labile 114
 carbon and N stimulate the turnover of more 115
 recalcitrant pools of carbon, releasing resources 116
 that were previously immobilized in that recalci- 117
 trant material and increasing belowground respi- 118
 ration from autotrophs and heterotrophs alike 119
 (Kuzyakov and others 2000). In contrast, when 120
 nutrients are readily available—as is the case when 121
 N is added in experimental conditions—nutrient 122
 acquisition does not depend upon those immobi- 123
 lized resources that are released through soil 124
 priming, and soil respiration decreases. Further, 125
 under conditions of N excess, added N can reduce 126
 rates of decomposition through the down-regula- 127
 tion of the activity of ligninolytic enzymes (Car- 128
 reiro and others 2000; Knorr and others 2005). 129

While the preponderance of evidence indicates 130
 that N addition suppresses soil respiration, other 131
 factors help to determine the magnitude of that 132
 effect. Duration of fertilization (Bowden and others 133
 2004; Burton and others 2004; Nohrstedt and 134
 others 1989), site fertility, and stand age (Kang and 135
 others 2016) can all affect the degree to which soil 136
 respiration is reduced by added N. Importantly, 137
 Bowden and others (2004) detected an initial in- 138
 crease in soil respiration in northern hardwood 139
 stands treated with added N followed by a long- 140
 term suppressive effect. Clarifying the effects that 141
 these variables have on soil respiration will im- 142
 prove understanding of this important source of 143
 atmospheric carbon. 144

Although temperate forests have long been as- 145
 sumed to be N limited, there is increasing evidence 146
 that both N and phosphorus (P) are important and 147
 may be co-limiting (Elser and others 2007; 148
 Vadeboncoeur 2010; Rastetter and others 2013). 149
 The study of Multiple Element Limitation in 150
 Northern Hardwood Ecosystems (MELNHE) in the 151
 White Mountains of New Hampshire is the longest- 152
 running NxP manipulation experiment in a tem- 153
 perate forest, and it provides an excellent setting for 154
 exploring relationships among nutrient availability, 155
 stand age, and many ecosystem characteristics. 156
 Among other findings, the MELNHE study has 157
 detected increased tree-diameter growth in re- 158
 sponse to added P (Goswami and others 2018) and 159
 fine-root growth responses to added N (Shan and 160

161 others 2022) or N plus P (Li and others 2023). To
 162 date, few studies outside of those conducted within
 163 the MELNHE experiment (Kang and others 2016;
 164 Bae and others 2015) have explored the interactive
 165 effects of site fertility and stand age on soil respi-
 166 ration, and few studies have tested how N avail-
 167 ability may interact with availability of P or other
 168 macronutrients, such as P (Zheng and others 2023).

169 In this study, we tested for effects of low-level N
 170 and P addition on soil respiration across stands of
 171 three age classes in the MELNHE experiment. Our
 172 dataset spans 10 years of treatments (2011–2020)
 173 and includes three seasons (spring, summer, and
 174 fall) of soil respiration measurements. Fine-root
 175 biomass was measured in 2015–2016 to serve as a
 176 covariate for soil respiration. We predicted that soil
 177 respiration would be highest in young stands (25–
 178 35 years old) prior to canopy closure and that the
 179 response to nutrient additions would be most pro-
 180 nounced in these stands. We expected a reduction
 181 in soil respiration due to N addition, as has been
 182 observed in similar experiments (Burton and others
 183 2004), but not due to P addition, in keeping with a
 184 recent meta-analysis of forest studies (Zheng and
 185 others 2023). With regard to temporal effects, we
 186 expected transient responses to treatments as var-
 187 ious ecosystem components adjusted to changing
 188 soil nutrient availability (Bowden and others
 189 2004). Finally, we predicted that the effect of N and
 190 P addition on soil respiration would vary by season,
 191 reflecting seasonal changes in root growth and soil
 192 microbial communities.

193 METHODS

194 Site Description

195 This study was conducted in 13 stands in the White
 196 Mountain National Forest of New Hampshire, USA
 197 (Table 1). Stands were of three successional stages:
 198 two early successional stands (19–21 years old at
 199 the beginning of the study in 2009), six mid-suc-
 200 cessional stands (24–39 years old in 2009), and five
 201 mature stands (80–126 years old in 2009). Stands
 202 were located in three sites: nine at Bartlett Exper-
 203 imental Forest (44°2–4' N, 71°9–19' W; elevation
 204 250–500 m), two at Hubbard Brook Experimental
 205 Forest (43°56' N, 71°44' W; elevation 500 m), and
 206 two at Jeffers Brook (44°2' N, 71°53' W; elevation
 207 730 m). Soils in all stands were formed in glacial
 208 drift and are predominantly Spodosols with a range
 209 of drainage characteristics (Bailey 2020; Vadebon-
 210 coeur and others 2012). Precipitation is evenly
 211 distributed throughout the year and amounts to
 212 about 145 cm annually (Hubbard Brook Watershed

Ecosystem Record 2021). Average daily tempera- 213
 214 tures at Hubbard Brook Experimental Forest range
 215 from –8 °C in January to 19 °C in July (USDA
 216 Forest Service 2020), but differences in elevation
 217 and aspect across the sites result in considerable
 218 temperature differences. Since 1965, total inor- 218
 219 ganic N deposition measured at Hubbard Brook W6
 220 has declined from a maximum of 10 kg ha⁻¹ y⁻¹ in
 221 1991 to a minimum of 2 kg ha⁻¹ y⁻¹ in 2020,
 222 averaging 4 kg ha⁻¹ y⁻¹ from 2009 to 2020,
 223 the period of our study (Hubbard Brook Watershed
 224 Ecosystem Record 2021). Phosphorus deposition is
 225 very low (0.04 kg P ha⁻¹ y⁻¹), usually below
 226 detection (Yanai 1992).

227 Tree species composition varied with stand age,
 228 as is typical in the northern hardwood forest type
 229 (Table 1 and Figure 1). Mature stands were repre-
 230 sentative of the typical northern hardwood forest:
 231 sugar maple (*Acer saccharum* Marsh.), yellow birch
 232 (*B. alleghaniensis* Britton), and American beech
 233 (*Fagus grandifolia* Ehrh.). Young and mid-suc-
 234 cessional stands consisted of red maple (*A. rubrum* L.),
 235 striped maple (*A. pensylvanicum* L.), pin cherry
 236 (*Prunus pensylvanica* L.f.), paper birch (*Betula pa-*
 237 *pyrifera* Marsh.), yellow birch, and American beech.

238 Each of the 13 MELNHE stands includes four
 239 treatment plots, each of which has received one of
 240 four nutrient treatments annually early in the
 241 growing season beginning in 2011: N addition (3 g
 242 N m⁻² y⁻¹ in the form of pelletized NH₄NO₃), P
 243 addition (1 g P m⁻² y⁻¹ in the form of granular
 244 NaH₂PO₄), N plus P (at the same rates), or neither
 245 (control). In most stands, plots measure
 246 50 m × 50 m including a 10 m buffer around a
 247 30 × 30 measurement area. Plots in two of the
 248 mid-aged stands have smaller measurement areas
 249 (20 m × 20 m), and three stands have smaller
 250 buffers (5 m to 7.5 m), due to the small size of the
 251 stands.

252 Soil Respiration

253 Soil respiration collars were constructed using
 254 20 cm I.D. PVC pipe, sharpened and inserted about
 255 3 cm into the forest floor. In 2009, five collars were
 256 installed in each plot, avoiding tree boles, boulders,
 257 large roots, and areas with severe drainage restric-
 258 tion. In 2010, these collars were moved to more
 259 systematic locations, and in 2014, two collars were
 260 added to each plot, for a total of seven collars per
 261 plot (Fahey and others 2021). Collars were rein-
 262 stalled and replaced as needed. Soil respiration was
 263 measured in all 13 stands from 2009 to 2020 (that
 264 is, including two pretreatment years) using the Li-
 265 COR 8100 Soil Respiration System (Licor Bio-

Fine-root biomass was measured in 2015–2016.

sciences, Lincoln, NE) following all manufacturer recommendations. The LiCOR 8100 was re-calibrated by the manufacturer every 2 years through the duration of the study. Measurements were made between 9 AM and 4 PM with most occurring between the hours of 10 AM and 2 PM (Fahey and others 2021). The stands in which measurements were made and the number of times those stands were visited varied across years because of limitations of funding, personnel, or site access. In all years, soil respiration was calculated from 90 s of CO₂ concentration measurements. Soil temperature was measured simultaneously with soil respiration using a handheld resistance thermometer at a depth of 10 cm adjacent to each collar. In total, 16,667 individual soil respiration readings were conducted over the course of the study.

Root Biomass

Soil cores for root biomass were collected in all stands in the late summer of 2015 (stands C1, C2, C4, C6, C7, C9) or 2016 (C3, C5, C8, HBM, HBO, JBM, JBO). Two locations ~ 1 m downslope from each of the original five soil respiration collars were sampled for a total of 10 cores from each plot.

When rocks or large roots obstructed the selected sampling location, a nearby alternate location was sampled. Cores were collected to a depth of 30 cm using PVC pipe with an inside diameter of 5 cm and divided by depth into two subsamples: 0 to 10 cm soil depth and 10 cm to 30 cm soil depth.

Fine roots (< 1 mm in diameter) were picked from the soil cores by hand. Roots 1–5 mm in diameter were also picked but are not reported here. Dead roots, which were identified by their lack of structural integrity, were excluded, as were herbaceous roots. Fine roots were oven-dried at 60 °C and weighed.

Data Analysis

Nutrient Addition and Stand Age

We tested for effects of nutrient addition and stand age on soil respiration with repeated-measures, mixed effect analyses of variance (ANOVA) using the 'lmer' function in the 'lme4' package (Bates and others 2015) in RStudio version 2022.07.2 + 576. Grouping years provided enough data to distinguish responses within seasons and over time, as the number of measurements in any

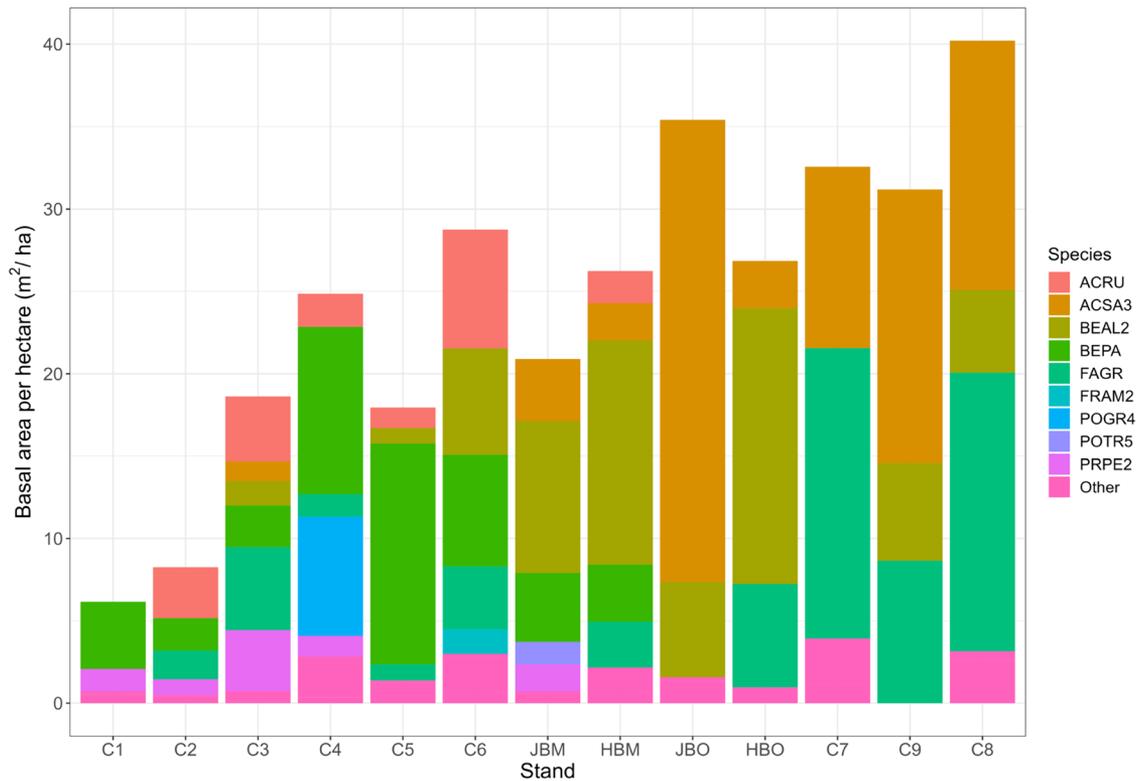

Figure 1. Basal area by species and stand. Stands are arranged from left to right in order of increasing stand age. Tree species are represented using USFS species codes: ACRU = *Acer rubrum*, ACSA3 = *A. saccharum*, BEAL2 = *B. alleghaniensis*, BEPA = *Betula papyrifera*, FAGR = *Fagus grandifolia*, FRAM = *Fraxinus americana*, POGR4 = *Populus grandidentata*, POTR5 = *P. tremuloides*, PRPE2 = *Prunus pensylvanica*.

313 given year and season was low. We consistently
 314 collected data in the summer, but due to the
 315 availability of personnel and access to study sites,
 316 spring and fall measurements were collected less
 317 frequently (Appendix A). The post-treatment da-
 318 taset was broken into four time periods to capture
 319 transient effects: 2011 (the 1st year of nutrient
 320 additions), 2012–2014, 2015–2017, and 2018–
 321 2020. Within each of those time periods, the data
 322 were analyzed separately by season: spring (March
 323 15–May 31), summer (June 1–August 30), and fall
 324 (August 31–November 26). With the exception of
 325 spring 2015–2017, measurements were collected in
 326 each season in each time period for a total of 11
 327 analysis periods.

328 The response variable was generated at the plot
 329 scale by first taking the median soil respiration rate
 330 for each measurement date because the mean was
 331 sensitive to the presence of outliers. Those values
 332 were then averaged within each analysis period to
 333 produce a single value for each plot in each analysis
 334 period, because we had only one estimate of root
 335 biomass measured in the summer of 2015 or 2016,
 336 not one for each visit. Fixed effects were N addi-

tion, P addition, stand age, and all their interac- 337
 tions. Stand age was a categorical factor, with 338
 stands C1 and C2 classified as early successional; 339
 C3, C4, C5, C6, HBM, and JBM classified as mid- 340
 successional; and C7, C8, C9, HBO, and JBO clas- 341
 sified as mature (Table 1). In addition to those fixed 342
 effects, average fine-root biomass (defined here as 343
 roots < 1 mm in diameter from 0 to 30 cm soil 344
 depth) and soil temperature were included as 345
 covariates. Random effects included stand 346
 nested within site. 347

Fine-Root Biomass 348

When the mixed effect ANOVA described above 349
 indicated a significant relationship ($p < 0.05$) be- 350
 tween soil respiration and fine-root biomass, those 351
 relationships were described with linear equations 352
 and coefficients of determination. In these analy- 353
 ses, the response variable was the average of the 354
 plot median soil respiration values in the analysis 355
 period of interest, and the fixed effect was the 356
 average plot root biomass per soil core. These 357
 analyses were conducted using the 'lm' function in 358
 R. 359

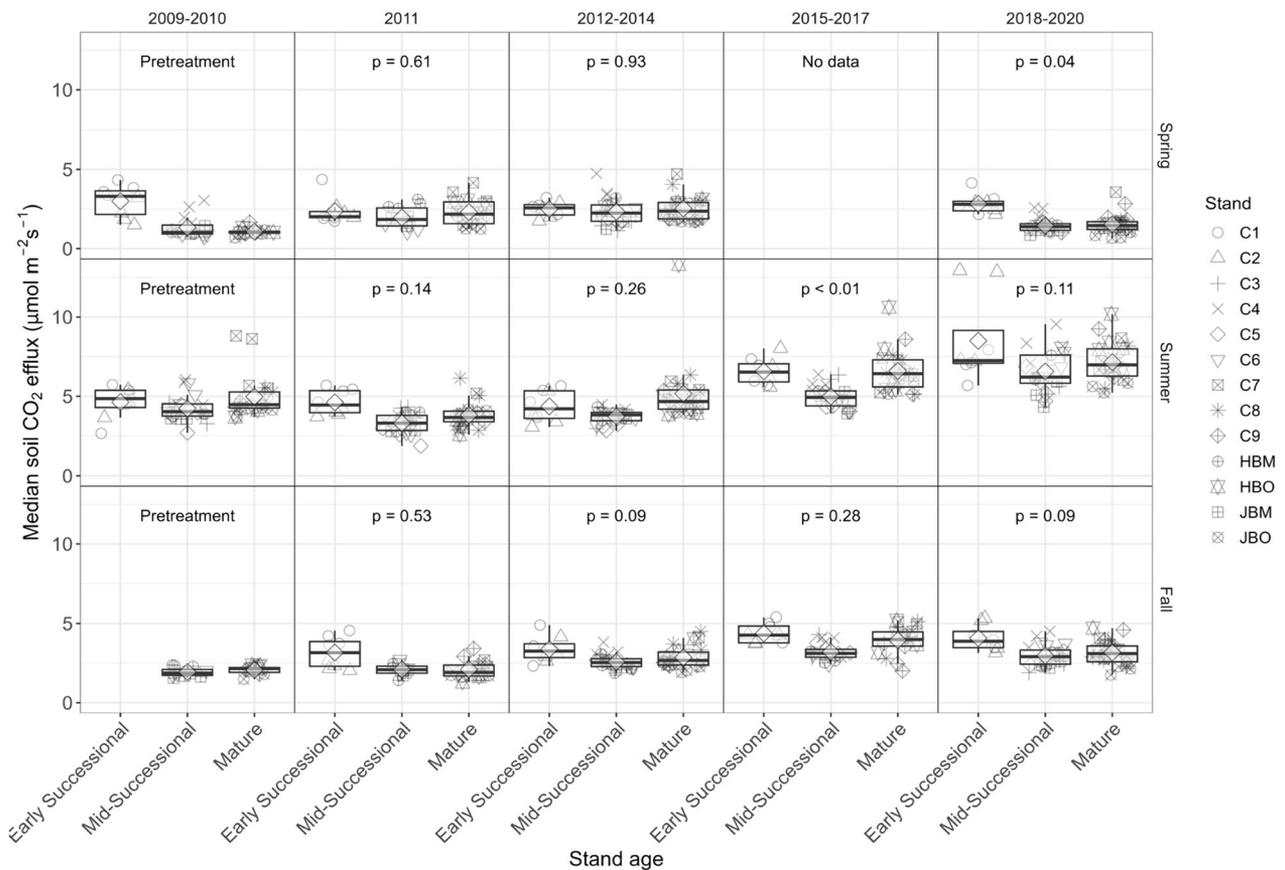

Figure 2 Boxplots of soil respiration by stand age and analysis period. Gray diamonds indicate the average for a given age class. **p** values indicate significance of the stand age effect in the larger ANOVA model.

360 Treatment effects on fine-root biomass were
 361 analyzed as the response variable in ANOVA of a
 362 mixed linear effect model generated using the
 363 'lmer' function in the 'lme4' R package (Bates and
 364 others 2015). This model included stand age, N
 365 addition, P addition, and the interaction of N
 366 addition and P addition as fixed effects. Random
 367 effects included stand nested within site.

368 *Changes in Soil Respiration Over Time*

369 We used a mixed effects linear model to quantify
 370 changes in soil respiration from 2009 to 2020 for
 371 each season. The response variable for this analysis
 372 was the plot median respiration value for the sea-
 373 son for each year, log transformed to achieve nor-
 374 mality of residuals. Fixed effects were year as a
 375 continuous variable, N addition, P addition, and
 376 their three-way interaction. A soil temperature
 377 covariate, calculated using the median soil tem-
 378 perature in each plot during each season in each
 379 year, was also included in the models. Stand nested
 380 within site was used as the random effect.

RESULTS

Soil Respiration as a Function of Stand Age and Fine-Root Biomass

384 Although we predicted that soil respiration would
 385 decrease with stand age, mid-successional stands
 386 had the lowest rates of soil respiration (averaging
 387 1.4–6.6 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ across stands, depend-
 388 ing on the analysis period) and early successional
 389 stands had the highest rates (2.5 to 8.5 $\mu\text{mol CO}_2$
 390 $\text{m}^{-2} \text{ s}^{-1}$); mature stands were intermediate (1.5 to
 391 7.2 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$). Differences with stand age
 392 were significant in both spring 2018–2020
 393 ($p = 0.04$ for the main effect of age) and summer
 394 2015–2017 ($p < 0.01$; Figure 2). Stands of differ-
 395 ent ages differed significantly in the response of soil
 396 respiration to N addition in four analysis periods.
 397 With only one exception among those four analysis
 398 periods, the suppressive effect of N was strongest in
 399 early successional stands, followed by mature
 400 stands, then mid-successional stands ($p \leq 0.06$ for
 401 the interaction of N x stand age, Figure 3).

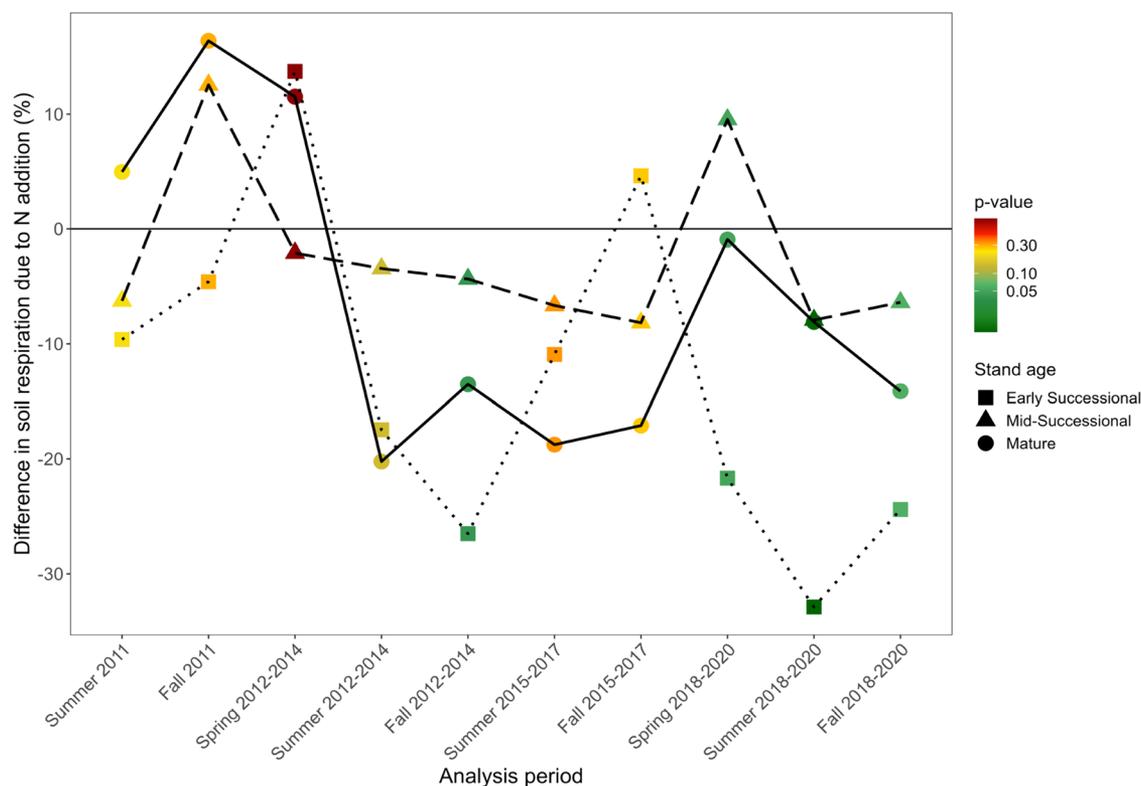

Figure 3. Magnitude of N effect on soil respiration by analysis period and stand age. Colors indicate p-values for analysis of the interaction effect of N and stand age upon soil respiration. No data were collected during spring 2015–2017.

402 Fine-root biomass, which was measured in 2015–
 403 2017, varied with stand age ($p = 0.01$ for the main
 404 effect of stand age), with the mid-successional
 405 stands having 30% lower root biomass than the
 406 young sands and 32% lower root biomass than the
 407 mature stands. As expected, soil respiration was
 408 positively correlated with fine-root biomass. This
 409 relationship was statistically significant in the
 410 summer 2012–2014 analysis period, when soil
 411 respiration increased by $1.33 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$
 412 per gram of fine-root biomass ($p = 0.10$ for the
 413 coefficient of fine-root biomass in linear regression,
 414 Figure 4). Fine-root biomass was not consistently
 415 affected by N addition ($p = 0.31$), P addition
 416 ($p = 0.70$), or their interaction ($p = 0.23$).

417 Soil N Effects on Soil Respiration

418 Nitrogen addition affected soil respiration either as
 419 a main effect or in interaction with another factor in
 420 five of 11 analysis periods (Table 2 and Figure 5). N
 421 addition resulted in significant declines in soil
 422 respiration during summer 2012–2014 (14%
 423 decline; $p = 0.01$ for the main effect of N), summer
 424 2015–2017 (13% decline; $p = 0.01$), and summer
 425 2018–2020 (13% decline; $p < 0.01$) analysis peri-
 426 ods (Figure 5). We also observed a significant effect

of N addition on soil respiration that was consis- 427
 tently strongest in early successional stands (Fig- 428
 ure 5, 22–33% suppression during summer 429
 analysis periods). This resulted in a significant 430
 interaction of N addition and stand age ($p = 0.05$ in 431
 spring and $p = 0.01$ in summer). 432

433 Soil P Effects on Soil Respiration

434 Soil respiration was consistently lower in P-treated 434
 plots than in their controls (Figure 6), but those 435
 differences were not sufficiently consistent to be 436
 statistically significant (Table 2), except during fall 437
 2012–2014, when respiration was 6% lower in 438
 plots treated with P ($p = 0.04$ for the main effect of 439
 P). Unlike the effect of N addition, differences 440
 across stand age classes in the effect of P addition on 441
 soil respiration were never statistically significant 442
 and were not consistent in direction (Figure 6). 443

444 Interactive Effects of N and P on Soil 445 Respiration

446 We found important interactive effects of N and P 446
 addition, whereby P tended to ameliorate the 447
 suppressive effects of N on soil respiration. In 448
 summer 2012–2014, soil respiration was 14% 449

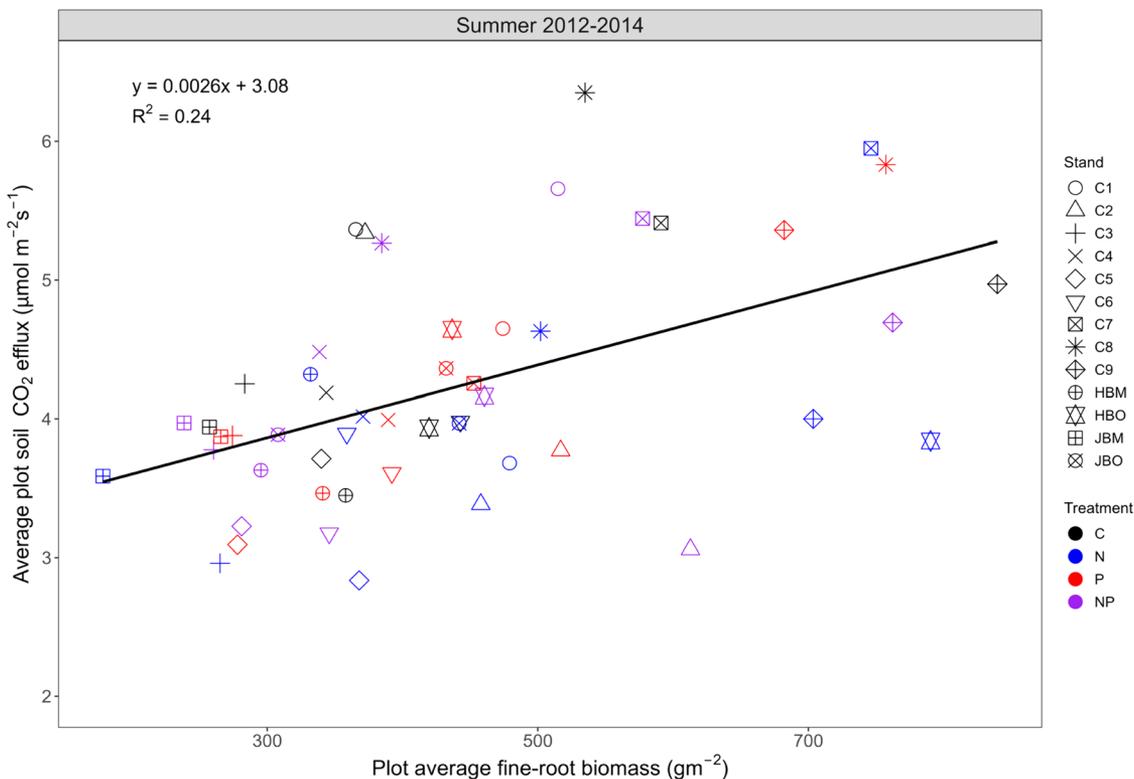

Figure 4. Average soil respiration during summers 2012–2014 as a function of root biomass for all 52 plots reported in this study.

450 lower in plots receiving N ($p = 0.01$ for the main
 451 effect of N, Figure 3). In that same analysis period,
 452 however, while N reduced soil respiration 24% in
 453 the absence of P, it reduced soil respiration by only
 454 1% when P was also added ($p = 0.01$ for the
 455 interaction of N x P in fall 2012–2014, the addition
 456 of N alone reduced soil respiration 20% while the
 457 addition of N in the presence of added P soil
 458 respiration was reduced by only 3% ($p < 0.01$ for the
 459 interaction of N x P). A significant N x P interaction
 460 was not detected in any other analysis period.
 461

462 Increases in Soil Respiration Over Time

463 Separate from the effects of N and P, we observed
 464 an unexpected increase in soil respiration over the
 465 course of this study (Figure 7). Between 2009 and
 466 2021, summer soil respiration increased by 7% per
 467 year for an 118% increase over that 13-year period
 468 ($p < 0.01$ for the coefficient of year in linear
 469 regression). Spring soil respiration increased 11%
 470 annually for a 232% increase over the course of the
 471 study ($p < 0.01$), and fall soil respiration increased
 472 5% per year for an increase of 89% over the course

of the study ($p < 0.01$). These time trends were
 independent of any treatment effects ($p \geq 0.37$ for
 all interactions of time, N, and P in linear regression),
 but temperature was positively correlated with soil
 respiration with each season ($p < 0.01$ for the
 coefficient of temperature in spring and fall; $p = 0.08$
 for summer).

480 DISCUSSION

481 Nitrogen Effects

482 Our finding that N additions reduced soil respiration
 483 was consistent with two analyses from our study sites
 484 early in the experiment. Pretreatment soil respiration
 485 was lowest in plots with high N mineralization and
 486 high nitrification (Bae and others 2015). After fertilization
 487 began in 2011 until 2013, soil respiration was most
 488 reduced in N-fertilized plots in stands with low
 489 pretreatment rates of N cycling, specifically N
 490 mineralization and litterfall N flux (Kang and others
 491 2016).

492 Other studies have similarly shown that increased
 493 soil N availability suppresses forest soil respiration.
 494 For example, 13 years of moderate N

Table 2. P Values for Main Effects and Interaction Effects on Soil Respiration by Analysis Period.

Cells shaded dark green contain p-values < 0.05, and cells shaded light green contain p-values > 0.05 and < 0.10.

495 additions (50 kgN/ha-y) at Harvard Forest in Mas-
 496 sachusetts caused a 15% reduction in soil respira-
 497 tion (Bowden and others 2004) similar to that
 498 observed after 8 years of low-level N additions (30
 499 kgN/ha-y) in northern hardwood forests in Michi-
 500 gan (Burton and others 2004). Together with these
 501 studies, our experiment indicates that a 13–15%
 502 reduction may be typical for the effect of long-term
 503 N additions on soil respiration in cool temperate
 504 broadleaf forests. Although we did not explore the
 505 mechanisms driving these responses of soil respi-
 506 ration to N addition, several possible causes have
 507 been suggested in the literature. Most studies sug-
 508 gest that suppression of heterotrophic respiration
 509 by added N is the primary explanation. For exam-
 510 ple, Burton and others (2004) indicated that N
 511 suppression of soil respiration in sugar maple for-
 512 ests was not caused by reduced root respiration, as
 513 root biomass, turnover and specific root respiration
 514 rate were unaffected by the treatments. Kuzaykov
 515 and others (2000) suggested that because N addi-
 516 tion reduces plants' dependence upon N resources
 517 generated by microbes, plants contribute less car-
 518 bon to the belowground community for the pur-
 519 pose of 'priming' decomposition. Because of this
 520 reduced carbon influx, effluxes of CO₂ are ulti-
 521 mately reduced. It is also possible that a reduction
 522 in microbial biomass or diversity in N-fertilized
 523 plots (Compton and others 2004; Allison and others
 524 2007; Frey and others 2004) could be responsible
 525 for declines in soil respiration. In a global meta-
 526 analysis, Treseder (2008) noted a roughly 15%
 527 reduction in microbial biomass under N addition,
 528 and this biomass response was correlated with soil
 529 respiration responses. Increased N availability may
 530 impede lignolytic enzyme activity (Carreiro and
 531 others 2000; Janssens and others 2010), especially
 532 in high lignin detritus (Knorr and others 2005).

Phosphorus Effects

533
 534 The absence of a main effect of P was consistent
 535 with two previous studies conducted in our study
 536 site early in the experiment, which both failed to
 537 detect an effect of P on soil respiration. The first
 538 study, conducted prior to the annual nutrient
 539 additions that began in 2011, found no effect of
 540 available soil P on soil respiration (Bae and others
 541 2015). The second study reported that between
 542 spring 2010 and September 2013, annual P addi-
 543 tions did not affect soil respiration (Kang and others
 544 2016). The absence of a detectable P effect over the
 545 duration of the present experiment is consistent
 546 with those findings. Similarly, two recent meta-
 547 analyses (Feng and Zhu 2019; Zheng and others
 548 2023) concluded that soil respiration is not signif-
 549 icantly affected by P addition in temperate forests.
 550 Notably, although forest production components
 551 typically increase with addition of N and P together,
 552 no significant response of soil respiration to com-
 553 bined NP addition was observed for a global meta-
 554 analysis (Zheng and others 2023). In contrast, P
 555 addition stimulated soil respiration in tropical for-
 556 ests, possibly reflecting very low soil P availability
 557 (Feng and Zhu 2019).

558 The addition of P in the MELNHE study, how-
 559 ever, had the effect of reducing resin-available soil
 560 N (Fisk and others 2014), and this is reflected in
 561 reductions in foliar N under P addition (Gonzales
 562 and Yanai 2019; Hong and others 2022). This effect
 563 of P on soil N may explain the NP interactions we
 564 observed, in which P addition significantly reduced
 565 the suppressive effect of N on soil respiration.

Stand Age Effects

566
 567 Previous studies of the relationship between stand
 568 age and soil respiration have found conflicting re-

Figure 5. Plot median soil respiration by treatment and analysis period. Gray diamonds indicate treatment means.

569 sults, with some reporting increases in soil respi- 593
 570 ration with age (Gough and others 2005), some 594
 571 reporting a decrease (Ewel and others 2011; Te- 595
 572 deschi and others 2006), and another reporting 596
 573 interannual variation in the effect of stand age on 597
 574 soil respiration (Irvine and Law 2002). Negative 598
 575 relationships between stand age and soil respiration 599
 576 have been attributed to higher soil temperatures in 600
 577 aggrading stands and the large quantities of post- 601
 578 harvest detrital residue (Ewel and others 2011).
 579 Positive relationships, on the other hand, are typi-
 580 cally attributed to increases in fine-root biomass
 581 (Gough and others 2005). In our stands, fine-root
 582 biomass was significantly lower in mid-successional
 583 stands than in early and late-successional stands
 584 (Table 1). As detailed in the Results, in most peri-
 585 ods there was a trend toward lowest soil respiration
 586 in mid-successional stands (Figure 2) corresponding
 587 to the fine-root biomass pattern.
 588 One notable interaction of stand age with treat-
 589 ment was observed. In analysis of summer data
 590 from 2018 to 2020, N effects varied by stand age
 591 ($p = 0.01$), with the suppression of soil respiration
 592 by added N being greatest in early successional

stands (32% in early successional stands versus 8%
 in mid-successional stands and 9% in mature
 stands). We speculate that this effect could be re-
 lated to intense competition for environmental re-
 sources, including soil nutrients, in the early
 successional stands (Fahey and others 1994). If the
 intensity of that competition was relieved by the
 addition of N, then belowground allocation by
 those trees might decrease.

Fine-Root Effects

602
 603 Respiration by tree roots comprises a significant
 604 proportion of soil respiration in forest ecosystems.
 605 For example, in mature northern hardwood forests
 606 at Hubbard Brook, root respiration contributed an
 607 estimated 39% of soil respiration (Fahey and others
 608 2005). Thus, a response of root growth or root bi-
 609 mass to nutrient additions would be expected to
 610 influence soil respiration. However, as noted earlier,
 611 Burton and others (2004) demonstrated that N
 612 suppression of soil respiration in four sugar maple
 613 stands was not caused by reduced root respiration.
 614 Similarly, although we found that fine-root biomass

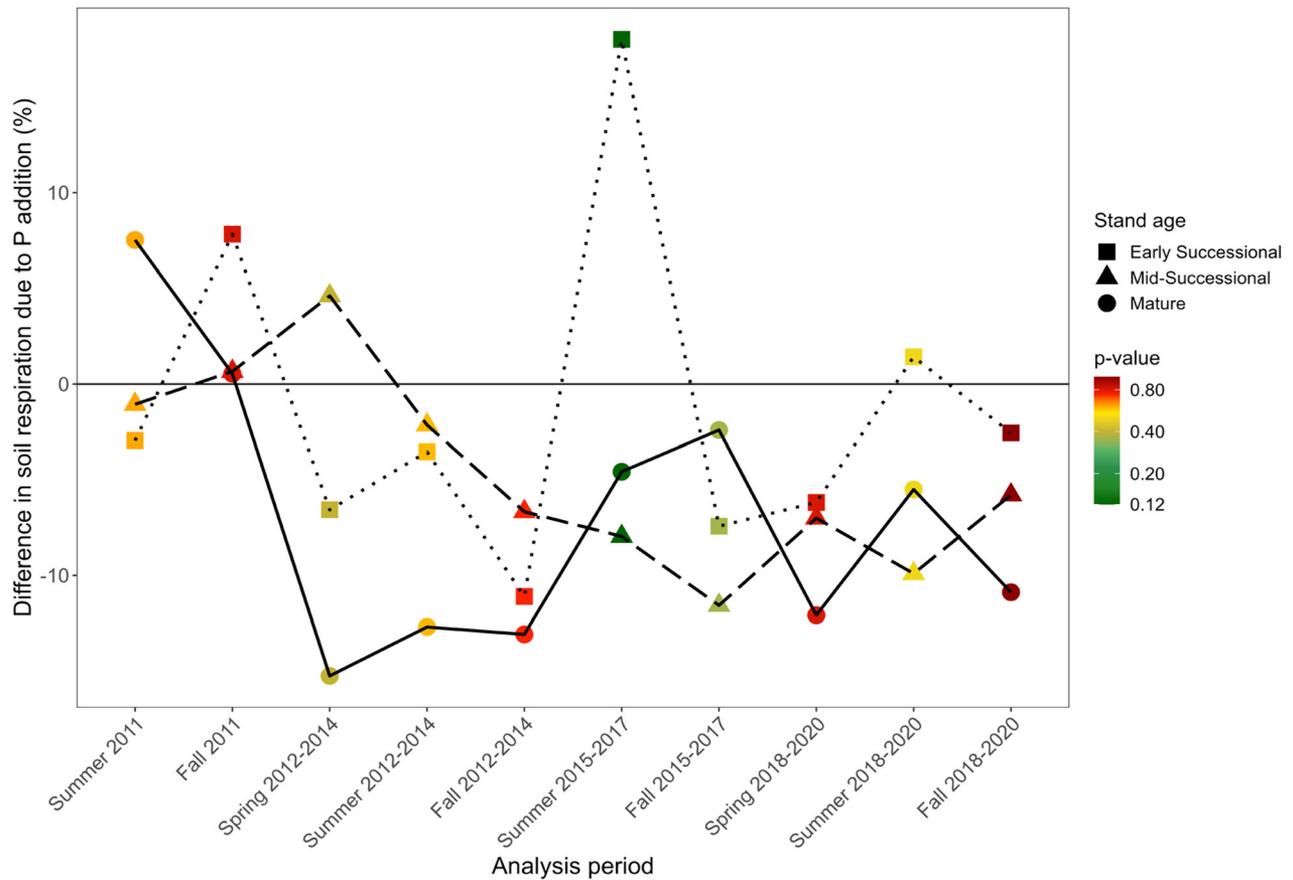

Figure 6. Magnitude of P effect on soil respiration by analysis period and stand age. Colors indicate p-values for analysis of the interaction effect of N and stand age upon soil respiration. No data were collected during spring 2015–2017.

615 was a significant predictor of soil respiration across
 616 our plots ($p = 0.10$), the reduction in soil respiration
 617 under N addition was not likely due to changes in
 618 root biomass, which actually increased in response
 619 to N addition (our unpublished data) and which was
 620 included as a covariate in the model.

621 Fine-root growth has been measured using in-
 622 growth cores in several of our stands. Surprisingly,
 623 given our observation that N suppresses soil respi-
 624 ration, in the three mature stands at Bartlett, fine-
 625 root growth was highest in plots receiving N alone
 626 (in 2013–2015; Shan and others 2022), while in
 627 two young stands (C1, C2 in 2017–2018) and three
 628 mid-age stands (C5, C6, HBM in 2021–2022), root
 629 growth was significantly greater in plots treated
 630 with both N and P than in control or single-nutri-
 631 ent addition plots (Li and others 2023; Jenn Butt,
 632 unpublished). Increases in growth with N or N + P
 633 addition would be expected to result in increased
 634 soil respiration, but we detected a suppressive effect
 635 of N on respiration. Thus, neither fine-root biomass
 636 nor fine-root growth explains the suppressive effect
 637 of N on soil respiration.

Temporal Effects

638 We expected transient changes and seasonal dif-
 639 ferences in the response of soil respiration to
 640 nutrient addition as various components of the
 641 process adjust to changes in nutrient availability
 642 (Bowden and others 2004; Zheng and others 2022).
 643 The N suppression of soil respiration by N was de-
 644 tected primarily in the summer season when soil
 645 temperature is highest and fluxes are greatest. This
 646 N suppression was consistent throughout most of
 647 the study period.
 648

649 We did not anticipate any long-term trend in soil
 650 respiration, and the causes of the clear and signif-
 651 icant 118% increase in summer soil respiration
 652 over the 10-year study are unknown. This
 653 temporal pattern was not explained by in-
 654 creases in soil temperature (Figure 4) treatment,
 655 or changes in instrumentation. A similar pattern
 656 has been observed at other locations in the Hub-
 657 bard Brook Experimental Forest (our unpublished
 658 data and Angela Possinger, personal communica-
 659 tion). One possible contributor is increasing

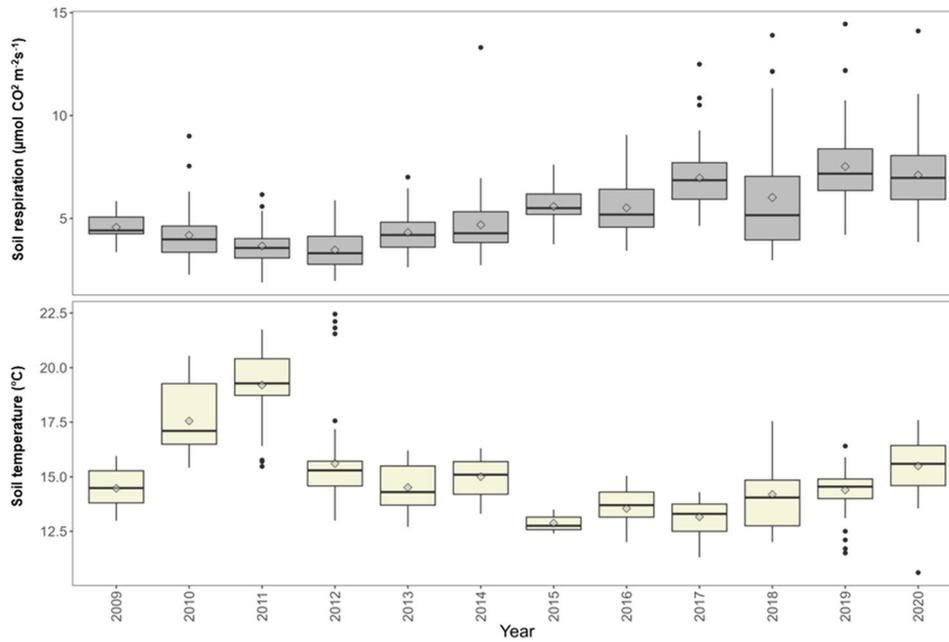

Figure 7. Distribution of plot median (a) soil respiration ($\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) and (b) soil temperature ($^{\circ}\text{C}$) for summer measurement periods. Gray diamonds represent annual means of these medians. Two high respiration values from 2018 ($28.6 \mu\text{mol m}^{-2} \text{ s}^{-1}$ and $38.5 \mu\text{mol m}^{-2} \text{ s}^{-1}$) are off the chart.

660 belowground carbon allocation due to a stimula-
 661 tion of photosynthesis by increasing atmospheric
 662 CO_2 (Ainsworth and Rogers 2007). Another possi-
 663 ble contributor is increasing fine-root biomass. The
 664 biomass of $< 5 \text{ mm}$ diameter roots increased by
 665 14% from 2008 to 2010 (pretreatment) to 2015–
 666 2016, but not at all from 2015–2016 to 2021–2022
 667 (our unpublished data). Thus, it is unlikely that
 668 increasing fine-root biomass was an important
 669 driver of the doubling of soil respiration from 2011
 670 to 2020 (Figure 7).

671
 672 **ACKNOWLEDGMENTS**

673 Many people make the MELNHE experiment pos-
 674 sible: the staff at Bartlett and Hubbard Brook
 675 Experimental Forests, including Chris Costello;
 676 Mary Hagemann, our administrative assistant at
 677 SUNY ESF; and dozens of graduate students and
 678 undergraduate interns who have contributed to the
 679 project over the years. Brendan Leonardi, Alex
 680 Young, and Shiyi Li were instrumental in collecting
 681 and managing the respiration data.

Author Query Form

Please ensure you fill out your response to the queries raised below and return this form along with your corrections

Dear Author

During the process of typesetting your article, the following queries have arisen. Please check your typeset proof carefully against the queries listed below and mark the necessary changes either directly on the proof/online grid or in the 'Author's response' area provided below

Query	Details Required	Author's Response
AQ1	Kindly check the keywords are correctly identified.	Corrections were made to capitalization.
AQ2	Please note that the figures are renumbered to ensure sequential ordering. Kindly check and confirm.	Figures are numbered correctly, but many of our references to them were incorrect
AQ3	References 'Fisk et al. (2015) and Pinheiro et al. (2023).' are given in list but not cited in text. Please cite in text or delete them from list.	Sorry about that! Removed references
AQ4	Figure [7] was received; however, no citation was provided in the manuscript. Please check and confirm the inserted citation of Fig is correct. If not, please suggest an alternative citation.	We added a citation to fit in the results.
